The hydrological analysis method in ArcGIS uses DEM data, possessed with an 8-meter resolution as input, and providing the output applicable to many sub-watersheds (BIG, 2021). The Central Citarum watershed is currently divided into 17 sub-watersheds, and the names correspond to the ID of the Citarum watershed management. Then, this research has generated a 20-year precipitation map by utilising data from six meteorological, climatological, and geophysical stations, specifically focusing on rainfall measurements in 2006–2018.

Kriging interpolation is utilised to create annual and monthly average rainfall maps. Annual and monthly evapotranspiration maps were acquired and cropped according to the research region (CGIAR, 2019).

Subsequently, another stage encompasses the mapping of plant water content and soil solum depth by integrating soil maps sourced from Sulaeman *et al.* (2013) with HWSD soil texture data (FAO, 2022). Based on the land cover map, a biophysical table and a water demand table were created. After that, each layer produced from the land cover map was converted to a raster format with a resolution of 30×30 m. These maps, together with the shapefile of the sub-watershed, were fed into the InVEST model. As the model's output, the program provides a map depicting the water yield and consumption for each sub-watershed.

The water balance model (Gan, Liu and Sun, 2021) and the mean annual average rainfall determine the water balance principles. The InVEST model, according to the research flowchart, requires specified data inputs. Tallis *et al.* (2011) used Equation (S1) to determine the yearly processed data for each pixel, represented as  $Y_{(x)}$ , relating to a certain land cover. In this InVEST model, the quantity of water flowing from the landscape is referred to as water yield, with average water volumes and yields calculated using sub-catchment-level water balancing principles (Gerstorf and Schupp (eds.), 2016). Water balance principles are established using the Budyko water balance model and the yearly average rainfall. Nugroho (2022) introduced Equation (S1) to compute yearly water yield data for each pixel, expressed as  $Y(x)$ , associated with a certain land cover category.

The annual  $WY$  for a given land use and land cover (LULC) at each pixel,  $Y_{(x)}$ , was set as follows:

$$Y_{(x)} = \left(1 - \frac{AET_{(x)}}{P_{(x)}}\right) P_{(x)} \quad (\text{S1})$$

where:  $AET_{(x)}$  = observed annual evapotranspiration at the specific pixel  $x$ ,  $P_{(x)}$  = yearly precipitation at the specific pixel  $x$ .

For LULC that has been vegetated (Fu, 1981),  $\frac{AET_{(x)}}{P_{(x)}}$  is the estimation of yearly precipitation on pixel  $x$  done in a spatially explicit way:

$$\frac{AET_{(x)}}{P_{(x)}} = 1 + \frac{PET_{(x)}}{P_{(x)}} - \left[1 + \left(\frac{PET_{(x)}}{P_{(x)}}\right)^{\omega}\right]^{\frac{1}{\omega}} \quad (\text{S2})$$

where:  $PET_{(x)}$  = pixel  $x$ 's potential evapotranspiration,  $\omega$  = non-physical characteristics that define the relationship between climate and soil conditions, often known as the coefficient of available water capacity for plants.

To determine possible evapotranspiration,  $PET_{(x)}$ , Equation (S2) was used:

$$PET_{(x)} = ET_{(x)} Kc_{(x)} \quad (\text{S3})$$

where:  $ET_{(x)}$  = reference evapotranspiration at the specified pixel  $x$ ,  $Kc_{(x)}$  = vegetation evapotranspiration coefficient at pixel  $x$ , which is related to its LULC categorisation (Zhang *et al.*, 2004).

The plant's available water capacity coefficient at each pixel, denoted as  $\omega_{(x)}$  as calculated using the approach presented by (Sánchez-Canales *et al.*, 2012) given by Equation (S4):

$$\omega_{(x)} = Z \frac{AWC_{(x)}}{P_{(x)}} + 1.25 \quad (\text{S4})$$

where:  $AWC_{(x)}$  = volume of available water capacity for the plant at each pixel (mm),  $Z$  = seasonality factor, also known as the Zhang coefficient, is an empirical constant that accounts for local precipitation patterns as well as other hydrogeological parameters.

In this study, a  $Z$  value of 4 was used, as recommended by Hamel and Guswa (2015) for tropical watersheds. This section includes both physical and non-physical characteristics of natural soil features in connection to climate. The available water capacity of soil refers to its ability to hold water that plants can use. It is represented as the  $AWC_{(x)}$  where  $(x)$  denotes the specific pixel or location (Hamel and Guswa, 2015). This metric is calculated using the plant available water capacity ( $PAWC$ ), minimum depth of the root limiting layer ( $Root1$ ), and the vegetation's root depth ( $Root2$ ). The following approach is used to perform the calculation:

$$AWC_{(x)} = \min(Root1, Root2) \cdot PAWC \quad (\text{S5})$$

The evapotranspiration of reference plants  $ET_{(x)}$  in the particular location reflects the local meteorological conditions, whereas  $Kc_{(x)}$  is influenced mostly by the land use and plant cover features unique to each pixel.

The actual evapotranspiration ( $AET$ ) in non-vegetated LULC regions, such as water bodies or settlements, is directly calculated based on the reference evapotranspiration. The quantity of rainfall determines the upper limit of  $ET_{(x)}$ , and the estimate approach is a)s follows:

$$AET_{(x)} = \min(Kc_{(x)} \cdot ET_{(x)}, P_{(x)}) \quad (\text{S6})$$

The modified Hargreaves equation (BIG, 2015) was used to compute reference evapotranspiration,  $ETo_{(x)}$  ( $\text{mm}\cdot\text{d}^{-1}$ ). When the following data are provided, this method is thought to produce more accurate findings than Penman–Monteith method:

$$ETo_{(x)} = 0.0013 \cdot 0.408Ra \left[ \left( \frac{T_{\max} + T_{\min}}{2} \right) + 17 \right] [(T_{\max} - T_{\min}) - 0.0123P]^{0.76} \quad (\text{S7})$$

where:  $Ra$  = extra-terrestrial solar radiation ( $\text{MJ}\cdot\text{m}^{-2}\cdot\text{d}^{-1}$ ),  $T_{\max}$  = average maximum daily air temperature ( $^{\circ}\text{C}$ ),  $T_{\min}$  = average minimum daily air temperature ( $^{\circ}\text{C}$ ),  $P$  = monthly precipitation ( $\text{mm}\cdot\text{d}^{-1}$ ).

The InVEST model validity was assessed by comparing it to the whole Wyoming dataset received from Liu *et al.* (2017). Linear regression analysis was used to compare the observed data to the estimated data generated by the model. Several statistical analyses were performed using the R program during the model validation phase depending on the study findings. The determination coefficient ( $R^2$ ), Pearson correlation ( $r$ ), and root mean square error ( $RMSE$ ) were all calculated as part of these investigations.

**Table S1.** Water supply ( $WS$ ), water demand ( $WD$ ), and water scarcity index ( $WSI$ ) in 2006 and 2018 based on sub-districts in the Central Citarum watershed
